The effects induced by long temporal correlations of the velocity gradients on the dynamics of a flexible polymer are investigated by means of theoretical and numerical analysis of the Hookean and finitely extensible nonlinear elastic (FENE) dumbbell models in a random renewing flow. For Hookean dumbbells, we show that long temporal correlations strongly suppress the Weissenberg-number dependence of the power-law tail characterising the probability density function (PDF) of the elongation. For the FENE model, the PDF becomes bimodal, and the coil–stretch transition occurs through the simultaneous drop and rise of the two peaks associated with the coiled and stretched configurations, respectively.

Key words: polymers

1. Introduction

The dynamics of a flexible polymer in a moving fluid depends strongly on the properties of the velocity gradients. A remarkable example is given by the coil–stretch transition in a planar extensional flow $v = (\epsilon x, -\epsilon y)$ (de Gennes 1974; Perkins, Smith & Chu 1997). This flow is characterised by a direction of pure compression and a direction of pure stretching with constant strain rate ϵ. The elongation of the polymer is controlled by the Weissenberg number $Wi = \epsilon \tau_p$, where τ_p is the longest relaxation time of the polymer. The value $Wi = 1/2$ marks the coil–stretch transition: for $Wi < 1/2$, the polymer remains coiled under the action of the entropic elastic force, whereas for $Wi > 1/2$ the drag force exerted by the flow overcomes the entropic force and the polymer unravels almost completely. As a consequence, the probability density of the extension, $p(R)$, has a single pronounced peak, whose position depends on Wi. For $Wi < 1/2$, the peak is in the neighbourhood of the equilibrium size of the polymer, R_0; for $Wi > 1/2$, the peak approaches the maximum length R_{max}.

The ability of a (non-uniform) laminar flow to deform an isolated polymer has now been demonstrated for various flow configurations (see, e.g. the reviews by Larson 2005 and Shaqfeh 2005). The corresponding problem for random flows was first studied by Lumley (1972, 1973), who observed that the strain tensor of an incompressible random flow always has a direction of stretching, although such direction fluctuates in time and in space. Lumley further remarked that the vorticity penalises polymer stretching, for it prevents the polymer from remaining aligned with the principal axes of the strain tensor. He then concluded that random flows can

† Email address for correspondence: dario.vincenzi@unice.fr

stretch polymers if the product of the Lagrangian correlation time of the strain tensor and the modulus of the maximum eigenvalue of the deformation tensor exceeds a critical value proportional to τ_p^{-1}. Groisman & Steinberg (2001) confirmed these conclusions by showing evidences of a significant amount of polymer stretching in a low-Reynolds-number random flow generated by viscoelastic instabilities.

In random flows, the time scale describing the stretching of line elements is the reciprocal of the maximum Lyapunov exponent λ. Hence, the appropriate definition of the Weissenberg number is $Wi = \lambda \tau_p$. Balkovsky, Fouxon & Lebedev (2000) and Chertkov (2000) related the deformation of a polymer in a random flow to the statistics of the stretching rate or, more precisely, to the entropy function associated with its probability density function (e.g. Crisanti, Paladin & Vulpiani 1993). Based on this analysis, Balkovsky *et al.* (2000) predicted the existence of the coil–stretch transition for any random flow with positive λ, and proposed the following explanation. For an infinitely extensible polymer ($R_{max} \to \infty$), the stationary probability density function (PDF) of the extension has a power-law tail: $p(R) \propto R^{-1-\alpha}$ for $R \gg R_0$, where α depends on the form of the entropy function. The exponent α is positive for $Wi < 1/2$, it decreases with increasing Wi and becomes negative as Wi exceeds $1/2$. Consequently, $p(R)$ is normalisable only for $Wi < 1/2$, whereas for $Wi \geqslant 1/2$, there is unbounded growth of the extension and the assumption of infinite extensibility becomes inadequate. This abrupt change in the statistics of the extension is interpreted as indicating the coil–stretch transition in random flows. The threshold $Wi = 1/2$ reproduces (to within a numerical factor) Lumley's criterion. (Balkovsky *et al.* (2000) defined the Weissenberg number as $Wi = 2\lambda \tau_p$ so that the coil–stretch transition occurs at $Wi = 1$.)

If the random flow is isotropic and has zero correlation time, $p(R)$ can be written explicitly and the behaviour predicted by Balkovsky *et al.* (2000) can be obtained by direct computation (Chertkov 2000; Thiffeault 2003; Celani, Musacchio & Vincenzi 2005; Martins Afonso & Vincenzi 2005). In this particular case, $\alpha = d(Wi^{-1} - 2)/2$, where d is the spatial dimension of the flow.

A polymer having finite maximum extension ($R_{max} < \infty$) reaches a stationary configuration at any Wi since the entropic force forbids extensions greater than R_{max}. According to the analysis of the infinitely extensible case, $p(R)$ is now expected to display a power-law behaviour $R^{-1-\alpha}$ for $R_0 \ll R \ll R_{max}$. In a short-correlated flow, the coil–stretch transition results from the combination of this power law and the cutoff at $R = R_{max}$: as Wi increases, the intermediate power law rises and the peak of $p(R)$ moves from R_0 to extensions near R_{max} (Martins Afonso & Vincenzi 2005). An important qualitative difference between extensional and random flows must nevertheless be emphasised. In the former case, $p(R)$ has a pronounced peak at an extension near either R_0 or R_{max} depending on whether Wi is less or greater than $1/2$. In the latter case, $p(R)$ has broad tails signalling the coexistence of coiled and stretched configurations with predominance of either configuration according to the value of Wi. In random flows, the coil–stretch transition is not as sharp as in the extensional case because of the random nature of the velocity gradient and the presence of vorticity.

The coil–stretch transition and the relation between the exponent α and the maximum Lyapunov exponent λ were investigated experimentally by Gerashchenko, Chevallard & Steinberg (2005) and Liu & Steinberg (2010). In these experiments, the statistics of the extension was measured by following a fluorescently labelled polymer in a random velocity field generated by elastic turbulence. The PDF of polymer extension was also investigated by means of direct numerical simulations of

the continuum equation for the polymer conformation tensor (Eckhardt, Kronjäger & Schumacher 2002; Boffetta, Celani & Musacchio 2003) and by means of Brownian dynamics simulations for elastic dumbbells (Celani *et al.* 2005; Davoudi & Schumacher 2006; Bagheri *et al.* 2010) or multi-bead chains (Watanabe & Gotoh 2010). The results of the simulations support the picture of polymer dynamics presented above.

The Weissenberg number suffices to determine the elongation of a polymer in laminar flows. By contrast, in random flows, an additional dimensionless number may influence the deformation of the polymer, namely the Kubo number $Ku = \lambda \tau_c$, where τ_c is the Lagrangian correlation time of the velocity gradient. The case $Ku = 0$ has been briefly reviewed above. In this paper, we examine the effect of a non-zero Ku and show that the dynamics at $Ku > 1$ differs significantly from the one predicted for short-correlated flows. To emphasise the basic physical mechanisms, we consider a simplified situation. The polymer molecule is modelled as an elastic dumbbell (Bird *et al.* 1977). This approximation is appropriate when attention is restricted to the extension of the polymer (Watanabe & Gotoh 2010). As for the random advection, we consider a two-dimensional linear renewing flow. In renewing flows, time is split into intervals of length τ_c and the velocities in different intervals are independent and identically distributed (e.g. Childress & Gilbert 1995, p. 320). Linear renewing flows were used by Zel'dovich *et al.* (1984) to study the kinematic dynamo effect; the magnetic field is actually stretched by the velocity gradient in the same way as an infinitely extensible polymer. The use of a linear renewing flow enables us to obtain semi-analytical results and to accurately compute the statistics of polymer extension with moderate numerical effort.

The remainder of the paper is divided as follows. In §2, we briefly review the elastic dumbbell model. In §3, we introduce the renewing random flow. The results are presented in §4. Finally, some conclusions are drawn in §5.

2. Elastic dumbbell model

An elastic dumbbell is composed of two beads joined by a spring. The beads represent the two ends of the polymer; the spring models the entropic force. For the sake of simplicity, we assume that the flow transporting the dumbbell is two-dimensional.

The vector separating the ends of the polymer, $\boldsymbol{R}$, satisfies the stochastic ordinary differential equation (e.g. Bird *et al.* 1977):

$$\dot{\boldsymbol{R}} = \sigma(t)\boldsymbol{R} - \frac{1}{2\tau_p} f(R)\boldsymbol{R} + \sqrt{\frac{R_0^2}{\tau_p}} \boldsymbol{\xi}(t), \qquad (2.1)$$

where $R = |\boldsymbol{R}|$ and $\boldsymbol{\xi}(t)$ is white noise, i.e. a Gaussian process with zero mean and two-time correlation $\langle \xi_i(t)\xi_j(t') \rangle = \delta_{ij}\delta(t - t')$. The three terms on the right-hand-side of (2.1) result from the drag force, the entropic elastic force and thermal noise, respectively. The 2×2 matrix $\sigma(t)$ is the velocity gradient evaluated along the trajectory of the centre of mass of the dumbbell: $\sigma_{ij}(t) = \partial_j v_i(t)$. The function $f(R)$ is identically equal to 1 for an infinitely extensible polymer (Hookean model) and has the form $f(R) = 1/(1 - R^2/R_{max}^2)$ for a finitely extensible polymer with nonlinear elasticity (FENE model). In the former case, $\boldsymbol{R}$ is defined on $\mathbb{R}^2$; in the latter case, $\boldsymbol{R}$ belongs to $[0, R_{max}) \times [0, R_{max})$.

Equation (2.1) holds under some assumptions on the dynamics of the beads. The velocity field is assumed to be linear at the size of the dumbbell. The drag on a bead is given by the Stokes law. Furthermore, hydrodynamic interactions between the beads and inertial effects are disregarded.

3. Linear renewing flow

According to the assumptions of the dumbbell model, in the reference frame of the centre of mass of the polymer, the velocity field is of the form: $v_i(\mathbf{r}, t) = \sigma_{ij}(t)r_j$. The velocity gradient $\sigma(t)$ is constant in each of the time intervals $I_n = [n\tau_c, (n+1)\tau_c)$, $n \in \mathbb{N}$. We denote by σ_n the (random) value taken by $\sigma(t)$ in I_n: $\sigma(t) = \sigma_n$ for all $t \in I_n$. The random matrices σ_n are identically distributed and statistically independent. We assume that, for a fixed n, σ_n is Gaussian, zero mean, statistically isotropic and traceless (so that the velocity field is incompressible). As a result, $\sigma(t)$ takes the form:

$$\sigma(t) = \frac{S}{2} \begin{pmatrix} \zeta_1(t) & \zeta_2(t) \\ \zeta_2(t) & -\zeta_1(t) \end{pmatrix} + \frac{\Omega}{\sqrt{2}} \begin{pmatrix} 0 & \zeta_3(t) \\ -\zeta_3(t) & 0 \end{pmatrix} \tag{3.1}$$

with S and Ω being positive constants. The elements $\zeta_i(t)$ satisfy: $\zeta_i(t) = \zeta_{i,n}$ for all $t \in I_n$, where the $\zeta_{i,n}$ are Gaussian random variables such that $\langle \zeta_{i,n} \rangle = 0$ for all i and n and $\langle \zeta_{i,n} \zeta_{j,m} \rangle = \delta_{ij}\delta_{nm}$ for all $i, j = 1, 2, 3$ and $n, m \in \mathbb{N}$. The mean-squared strain and rotation rates are S^2 and Ω^2, respectively. We set $\Omega = S$ to reproduce the relation holding for the solution of the Navier–Stokes equation (e.g. Frisch 1995, p. 20).

Strictly speaking, the flow considered is not statistically stationary in time. Nevertheless, over time ranges longer than τ_c, it can be considered as a good approximation to a stationary flow with correlation time τ_c owing to the invariance with respect to the transformation $t \to t + \tau_c$ and thanks to the independence of the matrices $\sigma(t)$ in different time intervals I_n (Zel'dovich *et al.* 1984). The δ-correlated flow (i.e. white-in-time noise) is recovered by letting τ_c tend to zero while holding $S^2\tau_c$ constant.

As mentioned in the Introduction, the elongation of a polymer is related to the statistics of the stretching rate of the flow. For a review on the entropy function and the generalised Lyapunov exponents in statistical physics, we refer the reader to the book by Crisanti *et al.* (1993). Here, we briefly recall some basic elements of the theory. If $\ell(t)$ denotes a fluid-line element, the stretching rate at time t is defined as $\gamma(t) = t^{-1} \ln[\ell(t)/\ell(0)]$. The maximum Lyapunov exponent is the long-time limit of the average stretching rate: $\lambda = \lim_{t \to \infty} \langle \gamma(t) \rangle$, where the average is taken over the realisations of $\sigma(t)$. The PDF of γ for long t takes the large-deviation form (Crisanti *et al.* 1993):

$$P(\gamma, t) \propto e^{-G(\gamma)t}, \tag{3.2}$$

where $G(\gamma)$ is the entropy function. $G(\gamma)$ is non-negative and attains its minimum value at the point λ. Equivalently, the stretching properties of the flow can be characterised by the generalised Lyapunov exponents, defined as the rate of growth of the moments of $\ell(t)$:

$$L(q) = \lim_{t \to \infty} \frac{1}{t} \ln \left\langle \left(\frac{\ell(t)}{\ell(0)} \right)^q \right\rangle. \tag{3.3}$$

The function $L(q)$ is the Legendre transform of $G(\gamma)$, $L(q) = \max_\gamma [\gamma q - G(\gamma)]$, and satisfies $L'(0) = \lambda$. For small q, $L(q)$ can be obtained by using the quadratic approximation $G(\gamma) \approx (\gamma - \lambda)^2/(2\Delta)$ so that $L(q) \approx \lambda q + \Delta q^2/2$.

For the linear renewing flow, we can compute $L(q)$ by adapting to the present problem the method described by Gilbert & Bayly (1992) (see also Childress & Gilbert 1995, pp. 322–326). A line element satisfies the equation:

$$\dot{\boldsymbol{\ell}}(t) = \sigma(t)\boldsymbol{\ell}(t). \tag{3.4}$$

Since $\sigma(t)$ is constant in I_n, the solution of (3.4) for $t \in I_n$ is: $\boldsymbol{\ell}(t) = e^{\sigma_n t}\boldsymbol{\ell}(n\tau_c)$. Hence

$$\boldsymbol{\ell}((n+1)\tau_c) = J_n\boldsymbol{\ell}(n\tau_c), \tag{3.5}$$

where $J_n = e^{\sigma_n \tau_c}$ is written

$$J_n = \frac{1}{2\omega_n}\begin{pmatrix} 2\omega_n c_n^+ + S\zeta_{1,n}c_n^- & (S\zeta_{2,n} + \sqrt{2}\Omega\zeta_{3,n})c_n^- \\ (S\zeta_{2,n} - \sqrt{2}\Omega\zeta_{3,n})c_n^- & 2\omega_n c_n^+ - S\zeta_{1,n}c_n^- \end{pmatrix} \tag{3.6}$$

with $\omega_n = \frac{1}{2}\sqrt{S^2(\zeta_{1,n}^2 + \zeta_{2,n}^2) - 2\Omega^2\zeta_{3,n}^2}$, $c_n^+ = (e^{\omega_n \tau_c} + e^{-\omega_n \tau_c})/2$, and $c_n^- = (e^{\omega_n \tau_c} - e^{-\omega_n \tau_c})/2$ (we remind the reader that $\zeta_{i,n}$ is the constant value taken by the random function $\zeta_i(t)$ in I_n). If ω_n is real, then J_n can be written in terms of hyperbolic functions; for a non-real complex ω_n, J_n involves trigonometric functions. By using the statistical isotropy of the flow and the fact that the matrices σ_n are identically distributed and independent for different n, it is possible to show the following relation (Gilbert & Bayly 1992; Childress & Gilbert 1995):

$$\frac{\langle\ell^q((n+1)\tau_c)\rangle}{\langle\ell^q(n\tau_c)\rangle} = \langle|J_n\boldsymbol{e}|^q\rangle_{I_n}, \tag{3.7}$$

where $\boldsymbol{e}$ is any constant unit vector and the average $\langle\cdot\rangle_{I_n}$ is taken over the statistics of the gradient in the interval I_n only. Iterating (3.7) yields: $\langle\ell^q(n\tau)\rangle = \langle\rho^q\rangle_{I_n}^n \ell^q(0)$ with $\rho^2 \equiv |J_n\boldsymbol{e}|^2 = \boldsymbol{e}^T J_n^T J_n\boldsymbol{e}$. It follows that $L(q)$ and λ can be written as

$$L(q) = \tau_c^{-1}\ln\langle\rho^q\rangle_{I_n} \quad\text{and}\quad \lambda = \tau_c^{-1}\langle\ln\rho\rangle_{I_n}. \tag{3.8}$$

Given that the σ_n are identically distributed, the average can be taken over any interval I_n. Equations (3.8) provide a simple way to compute the function $L(q)$ and the Lyapunov exponent. The behaviour of λ as a function of τ_c is reported in figure 1. The following asymptotic behaviours hold (Chertkov et al. 1996):

$$\lambda \sim \frac{S^2\tau_c}{4} \quad (\tau_c \to 0) \quad\text{and}\quad \lambda \sim \text{Re}\langle\omega_n\rangle_{I_n} = \sqrt{\frac{\pi}{2}}\frac{S}{2}\sqrt{\frac{S^2}{S^2 + 2\Omega^2}} \quad (\tau_c \to \infty). \tag{3.9}$$

For $\Omega = S$, one obtains $\lambda \sim \sqrt{\pi/6}\,S/2$ as $\tau_c \to \infty$. Thus, the Lyapunov exponent becomes independent of τ_c for large τ_c, and the convergence to the asymptotic value is exponential. By contrast, the variance Δ monotonically increases like $\Delta \sim S^2\tau_c/4$ both for small and large τ_c (Chertkov et al. 1996), and therefore the generalised Lyapunov exponents do not saturate to a constant value (figure 1). We stress the fact that the above asymptotic behaviours hold for any two-dimensional random flow that is incompressible and statistically isotropic and not only for the renewing flow.

4. Statistics of polymer extension

In order to investigate the influence of temporal correlations of the velocity gradients on the dynamics of polymers, we numerically integrated (2.1) for the elastic dumbbell model, where the velocity gradients were determined by (3.1). We computed the
FIGURE 1. Lyapunov exponent as a function of τ_c (circles). Dashed and dotted lines represent the asymptotic behaviours (3.9) for $\tau_c \to 0$ and $\tau_c \to \infty$, respectively. Inset, generalised Lyapunov exponents $L(q)$ for three values of Ku. Note that $L(-d) = L(0) = 0$ in agreement with the properties of the generalised Lyapunov exponents proved by Zel'dovich *et al.* (1984).

PDF of the polymer elongation R for various values of Ku and Wi. The numerical integration has been performed using the predictor–corrector scheme proposed by Öttinger (1996) for the FENE model and the stochastic Runge–Kutta algorithm introduced by Honeycutt (1992) for the Hookean model. The statistics of polymer elongation has been computed by following the dynamics of a single dumbbell for 10^7 time intervals I_n.

Within the Hookean model, the PDF of the extension behaves like $p(R) \propto R^{-1-\alpha}$ for $R \gg R_0$ (Balkovsky *et al.* 2000). The coil–stretch transition is identified by the change of sign of α, which occurs at $Wi = 1/2$. The effects of the temporal correlation of the velocity gradients can be quantified through the dependence of α on the Kubo number. The numerical simulations of the Hookean model show that for small values of Ku the tail of $p(R)$ is almost independent of Ku; conversely, for $Ku \gtrsim 1$, the tail rises as Ku increases and approaches the slope -1 (figure 2). Because of long temporal correlations, even polymers with a short relaxation time occasionally experience significant stretching events, and this effect produces a power-law tail close to the coil–stretch transition also for small values of Wi.

This intuitive idea can be rationalised by the following argument. The exponent α determines the lowest order such that $\langle R^\alpha \rangle$ diverges and satisfies $\alpha = 2\tau_p L(\alpha)$ (Boffetta *et al.* 2003). For Wi near $1/2$, α is not far from zero and it is appropriate to use the quadratic approximation for $L(q)$. $\alpha = 2\tau_p L(\alpha)$ then yields (Balkovsky *et al.* 2000):

$$\alpha = \frac{\lambda}{\Delta}\left(\frac{1}{Wi} - 2\right). \tag{4.1}$$

While the dependence of α on the Weissenberg number is contained entirely in the second factor, the Kubo number enters the expression for α through the ratio λ/Δ.
FIGURE 2. PDFs of polymer elongation, $p(R)$, for the Hookean model at $Wi = 1/4$. Note the power-law behaviours $p(R) \propto R^{d-1}$ for $R \ll R_0$ and $p(R) \propto R^{-1-\alpha}$ for $R \gg R_0$. Inset, exponent α as a function of Ku. Here $\alpha_0 = \lim_{Ku \to 0} \alpha$. Dash-dotted and dashed lines are the asymptotic behaviours (4.1) and (4.2) for $Ku \to 0$ and $Ku \to \infty$, respectively.

For the linear renewing flow, the asymptotic behaviours discussed in §3 give:

$$\lambda/\Delta \sim 1 \quad (Ku \to 0) \qquad \text{and} \qquad \lambda/\Delta = O(Ku^{-1}) \quad (Ku \to \infty). \qquad (4.2)$$

One obtains that for small values of Ku the tail of $p(R)$ is independent of Ku, whereas $\alpha = O(Ku^{-1})$ as Ku is increased, in agreement with our numerical findings.

Although for an infinitely extensible polymer, $p(R)$ is normalisable only for $\alpha > 0$ (equivalently for $Wi > 1/2$), the calculation leading to the power-law behaviour remains formally valid also if $\alpha < 0$ ($Wi > 1/2$). In this case, the stationary PDF of the extension exists only if the nonlinearity of the elastic force is taken into account, and the power-law prediction is expected to hold for intermediate extensions $R_0 \ll R \ll R_{max}$. To allow the development of the intermediate power law, we performed numerical simulations of the FENE model at artificially high R_{max}/R_0. For $Wi < 1/2$, the results agree with those obtained for the Hookean model (figure 3a). For $Wi > 1/2$, an increase of Ku produces a decrease of the intermediate slope of $p(R)$, which can be negative even for very large Wi (figure 3b). According to (4.2), near $Wi = 1/2$, the range of variation of α as a function of Wi can be made arbitrarily small by increasing Ku, to the extent that the intermediate slope of $p(R)$ becomes almost independent of Wi (figure 4). Our findings show that the picture of a coil–stretch transition associated with the increase of the intermediate slope of $p(R)$ does not hold in a long-correlated flow. At large Ku, the appearance of the stretched state occurs through the drop of the maximum at $R \approx R_0$ and the simultaneous rise of a second maximum near R_{max} (figure 4).

For realistic values of R_{max}/R_0, it is difficult to detect a clean power law at intermediate extensions and the above scenario becomes even more relevant. The numerical simulations of the FENE model for $R_{max}/R_0 = 20$ show that, for short-correlated flows ($Ku \ll 1$), the coil–stretch transition manifests through the gradual widening of $p(R)$ and the displacement of its maximum from values close to R_0
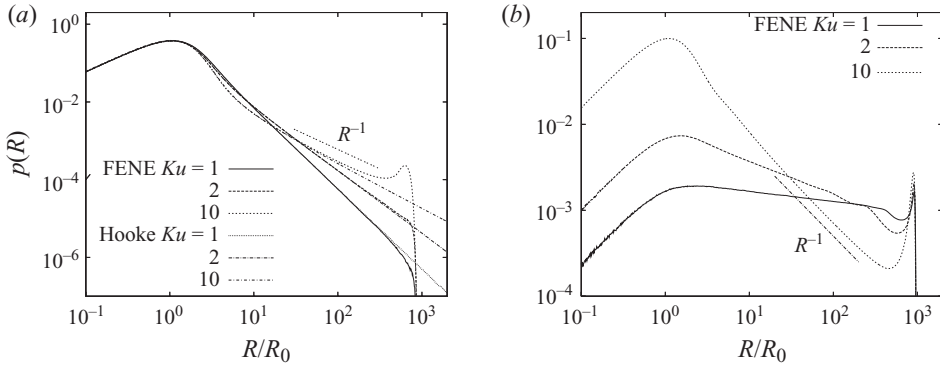

FIGURE 3. PDFs of polymer elongation for the FENE model at various values of Ku for $Wi = 1/4$ (*a*) and $Wi = 1$ (*b*). The maximum extension is set to $R_{max} = 10^3 R_0$.

FIGURE 4. PDFs of polymer elongation for the FENE model at various values of Wi in a long-correlated flow ($Ku = 10$). The maximum extension is set to $R_{max} = 10^3 R_0$.

towards values close to R_{max} (see figure 5*a*). This behaviour is in agreement with the theoretical prediction for the δ-correlated isotropic flow (Martins Afonso & Vincenzi 2005) and with recent experimental measurements of polymer elongation in a random shear flow (Liu & Steinberg 2010). For long-correlated flows ($Ku \gtrsim 1$), the dependence of $p(R)$ on Wi is very different. In this case, increasing Wi at fixed Ku rather produces the drop of the peak at R_0 and the simultaneous formation of a second peak near R_{max} (see figure 5*b*). The PDF of the extension is bimodal and the two maxima are clearly distinct: intermediate extensions are much less likely than in the small-Ku case.

The shape of $p(R)$ for large Ku can be explained intuitively as follows. If the Lagrangian correlation time of the velocity gradient is long, a typical trajectory of a polymer is composed of long portions where the gradient can be thought of as frozen with a fixed direction of stretching. Some of those portions will be characterised by
FIGURE 5. PDFs of polymer elongation for the FENE model, at various Wi numbers, in a short-correlated flow ($Ku = 10^{-2}$) (a) and in a long-correlated flow ($Ku = 10$) (b). The maximum extension is set to $R_{max} = 20R_0$.

a weak stretching rate, some by a strong one. The response of the polymer to the velocity gradient along one of those portions of the trajectory will be similar to the response that a polymer would have in an extensional flow with strain rate comparable to the stretching rate. As mentioned earlier, the PDF of R in an extensional flow has a sharp peak either at small extensions or at long extensions depending on the strain rate, and intermediate extensions are very unlikely. Therefore, the evolution of an isolated polymer at large Ku consists of a sequence of long deformation events, whose intensity can produce either a coiled or a highly stretched extension, whence the bimodal shape of $p(R)$.

5. Conclusions

We have studied the influence of long temporal correlations on the dynamics of a Hookean dumbbell and of a FENE dumbbell in a two-dimensional random renewing flow. The time correlation of this simple model flow can be changed arbitrarily, and this property enabled us to obtain semi-analytic predictions for the Kubo-number dependence of the statistics of polymer elongations. It is known that the PDF of the elongation of Hookean dumbbells is characterised by a power-law tail and that

this power law also describes the behaviour of the PDF of FENE dumbbells at intermediate elongations. We have shown that in the long-correlated limit ($Ku \to \infty$), the power-law tail becomes almost insensitive to Wi and its slope is not an effective indicator for the coil–stretch transition. In the case of the FENE model, the long temporal correlations strongly affect the shape of the PDF, which shows two distinct maxima corresponding to the coiled and stretched configurations. For $Ku \gg 1$, we have found a new scenario for the coil–stretch transition, which occurs through the drop of the peak at R_0 and the simultaneous rise of the second peak near R_{max}.

Our findings can be understood in terms of basic properties of long-correlated flows, and the underlying mechanism does not rely on the peculiar choice of the model flow used in our study. It is therefore arguable that the phenomena discussed here could be observed also in realistic flows. In particular, it would be interesting to investigate by means of numerical simulations or experimental measurements whether the presence of long-lived structures in high-Reynolds-number flows could result in the appearance of the two-peak coil–stretch transition scenario depicted here.
